ABSTRACT

Compared to hardware prefetching, the prefetching in Web systems faces quite high branching factor. Decision points mostly bifurcate the control flow tree in hardware due to the predominant if-then like program constructs. In contrast, in web there is no limit on the number of links in a page. In the case of hardware quite often all the parallel branches are prefetched-- and in some cases condition can be pre-evaluated to determine the prefetch path. Neither is practical for web systems. There is critical for web systems to carefully evaluate all prefetch options. This report contains few analytical results, which show how to rank prefetch paths in various hyper linked graphs shown in Fig-A-D. It seems in most cases optimum prefetch path should depend both on the link transition probability as well as loading time of the component --rather than just the former.

1 Optimization Criterion

In a hyper-graph G, Lets U=(a_1,a_2,a_3,...a_l), where u_i∈G, is the anchor sequence-- the sequence of nodes followed by a user. Let’s Γ is the loading sequence in which the nodes are loaded in the cache (Clearly, U ⊆ Γ ⊆ {nodes in G}). Let p_i is the estimated probability that a user traverses a node a_i in roaming sphere G, and T_{L,i} is the time the node a_i is fetched and T_{P,i} is the time spent by the user in that node. Thus, we define an overall penalty function-- the expected cumulative read-time lag:

\[ T(\Gamma | U) = \sum_{i} p_i \max \{T_{L,i} - (T_{L,i-1} + T_{P,i-1})\} \]

...(1)

The objective is to find the loading sequence Γ that will minimize the expected penalty E(T(Γ|U)). It is important to note that this function optimizes with respect to all probable transitions of U, weighted by their transition probability.
2 Some Analytical Results

**Theorem-1 (Branch Decision):** Let \( A = n_i \) is the current anchor point with direct transition paths to a set of candidate nodes \( n_1, n_2, \ldots, n_m \), such that \( T_i \) is the estimated loading times of node \( n_i \), and 
\[
Pr[a_{n+1}=n_i \mid a_n=A] \text{ is the conditional link transition probability, then the average delay is minimum if the links are prefetched in-order of the highest priority } Q_n, \text{ where:}
\]
\[
Q_j = \frac{Pr[a_{n+1}=n_i \mid a_n=A]}{T_i} \quad \ldots (A.1)
\]

Proof: Let us consider two pre-fetching sequences \( \text{Seq1} = [n_0, n_1, n_2, \ldots, n_{m-1}, n_m, n_{m+1}, \ldots, n_r, n_{r+1}, \ldots, n_n] \) and \( \text{Seq2} = [n_0, n_1, n_2, \ldots, n_{m-1}, n_m, n_{m+1}, \ldots, n_r, n_{r+1}, \ldots, n_n] \), where \( m < r \). These two sequences are identical, except only two of the nodes \( n_m \) and \( n_r \) have been switched their positions. We also note that the nodes loaded prior to the \( m \) node and the nodes loaded after the \( r \) nodes are identical in both the sequences. We use the following expressions to denote the cost function due to these two nodes:

\[
C_{\text{prev.}} = \sum_{j=0}^{m-1} \left\{ p_j \sum_{i=0}^{j} T_i \right\}, \quad \text{and } C_{\text{post.}} = \sum_{j=r+1}^{N} \left\{ p_j \sum_{i=0}^{j} T_i \right\}.
\]

We also use \( T_p = \sum_{i=0}^{m-1} T_i \) to denote cumulative load time of nodes loaded before \( n_m \). Let 's also denote \( p_i = Pr[a_{n+1}=n_i \mid a_n=A] \). Thus, the expected cost factor for sequence 1 is given by:

\[
C_{\text{seq1}} = C_{\text{prev.}} + p_m \cdot (T_p + T_m) + p_{m+1} \cdot (T_p + T_m + T_{m+1}) + \ldots + p_r \cdot (T_p + T_m + \ldots + T_r) + C_{\text{post.}}
\]

\[
= C_{\text{prev.}} + p_m \cdot (T_p + T_m) + \sum_{j=m+1}^{r} \left\{ p_j \cdot (T_p + \sum_{i=j}^{r} T_i) \right\} + p_r \cdot (T_p + T_m + \ldots + T_r) + C_{\text{post.}}
\]

\[
= T_m \cdot \left\{ \sum_{j=m+1}^{r} p_j \right\} + p_r \cdot (T_m + \ldots + T_r) + K_1
\]

Where:

\[
K_1 = C_{\text{prev.}} + p_m \cdot (T_p + T_m) + \sum_{j=m+1}^{r} \left\{ p_j \cdot (T_p + \sum_{i=j}^{r} T_i) \right\} + p_r \cdot (T_p + T_r) + C_{\text{post.}}
\]

In a similar way, the cost for the sequence 2 is given by:

\[
C_{\text{seq2}} = C_{\text{prev.}} + p_r \cdot (T_p + T_r) + p_{m+1} \cdot (T_p + T_r + T_{m+1}) + \ldots + p_{r-1} \cdot (T_p + T_r + \ldots + T_{r-1}) + p_m \cdot (T_p + T_m + \ldots + T_r) + C_{\text{post.}}
\]

\[
= C_{\text{prev.}} + p_r \cdot (T_p + T_r) + \sum_{j=m+1}^{r} \left\{ p_j \cdot (T_p + \sum_{i=j}^{r} T_i) \right\} + p_m \cdot (T_p + T_m + \ldots + T_r) + C_{\text{post.}}
\]

\[
= T_r \cdot \left\{ \sum_{j=m+1}^{r} p_j \right\} + p_m \cdot (T_m + \ldots + T_r) + K_2
\]
Where,
\[ K_2 = C_{prev} + p_r \cdot (T_p + T_r) + \sum_{j=m+1}^{r-1} \left\{ p_j \cdot (T_p + \sum_{i=m+1}^{j} T_i) \right\} + p_m \cdot (T_p + T_m) + C_{post} \]

We now compare the estimated delay costs of these sequences, and show that under the given condition (A.1) one will be always lesser than the other. Both (A.2) and (A.3) can be expanded as following:
\[ C_{seq1} = T_m \cdot (p_{m+1} + \ldots + p_{r-1}) + p_r \cdot (T_m + \ldots + T_{r-1}) + K_1 \]
\[ C_{seq2} = T_r \cdot (p_{m+1} + \ldots + p_{r-1}) + p_m \cdot (T_{m+1} + \ldots + T_r) + K_2 \]

Rearrangement of the terms will show that \( K_1 = K_2 \). Additionally, if:
\[ \frac{p_m}{T_m} > \frac{p_{m+i}}{T_{m+i}} \]

Then \( T_m \cdot p_{m+i} \leq p_m \cdot T_{m+i} \), and since \( r > m \), \( p_r \cdot T_{r-i} \leq T_r \cdot p_{r-i} \), for all positive \( i \). Thus, the left terms of (A.2) are smaller than the middle terms of (A.3). Similarly, the middle terms of (A.2) are smaller than the left terms of (A.3). Thus, \( T_m \cdot (p_{m+1} + \ldots + p_{r-1}) \leq p_m \cdot (T_{m+1} + \ldots + T_r) \) and \( p_r \cdot (T_m + \ldots + T_{r-1}) \leq T_r \cdot (p_{m+1} + \ldots + p_{r-1}) \). Thus, \( C_{seq1} \leq C_{seq2} \) is always true under condition A.4, which is the priority given is equation (A.1) of individual nodes (proved).

**Corollary-2.1 (Sequence Decision):** If two nodes are in a sequence, then the preceding node has to be loaded first.

Proof: below we provide a direct proof of this intuitive corollary. Let nodes \( n_1 \) and \( n_2 \) are in a sequence, \( n_1 \) preceding \( n_2 \). We compare the costs for two sequences Seq1= \([n_1, n_2, \ldots]\) Seq2= \([n_2, n_1, \ldots]\). Since, \( n_2 \) is traversed only after \( n_1 \) the state probabilities \( p_2 \leq p_1 \). The response delay count begins for the second node, after the first node is loaded and then read i.e. at time \((T_1+R_i)\). Thus, the cost of first sequence is given by:
\[ C_{seq1} = p_1 \cdot T_1 + p_2 \cdot \max\{T_1 + T_2 - (T_1 + R_i), 0\} = p_1 \cdot T_1 + p_2 \cdot \max\{T_2 - R_i, 0\} \]

.....(B.1)

Similarly, the cost for the second sequence is given by:
\[ C_{seq2} = p_1 \cdot (T_1 + T_2) + p_2 \cdot \max\{T_1 - (T_1 + T_2 + R_i), 0\} \]

= \[ p_1 \cdot (T_1 + T_2) \]

Since, the second node is loaded before the first node so it will be immediately available after the first node is read. If \( \max\{T_2 - R_i, 0\} = 0 \) then, \( 0 \leq p_1 \cdot (T_1 + T_2) \). Thus, \( C_{seq1} \leq C_{seq2} \). On the other hand, if \( \max\{T_2 - R_i, 0\} = T_2 - R_i \), then also, \( p_1 \cdot T_1 + p_2 \cdot (T_2 - R_i) \leq p_1 \cdot (T_1 + T_2) \), or \( p_1 \cdot (T_2 - R_i) \leq p_1 \cdot T_2 \). Since, \( p_2 \leq p_1 \) and \( T_2 - R_2 \leq T_2 \). Thus, for this case also \( C_{seq1} \leq C_{seq2} \). Note: If node 2 can be reached via a second path, then state probability \( p_2 \leq p_1 \) may not be true (proved).
Theorem-2 (Tree Decision): If the sequence \( \{n_1, n_2, n_3, \ldots, n_d\} \) are the nodes in the path in a tree from the current anchor \( A = n_0 \) to a candidate node \( n_d \) at depth \( d \) and \( T_d \) is its estimated loading time, then the priority \( Q_d \) is given by the product of the conditional transition probabilities along the path such that:

\[
Q_d = \frac{\prod_{i=0}^{d} \Pr[a_{i+1} = n_{i+1} \mid a_i = n_i]}{T_d} \tag{C.1}
\]

Proof: Without loss of generality, the question we will address in this proof is that should we bring a node from depth \( d \) before fetching a node from depth 1? Consequently, we compare two pre-fetching sequences \( \text{Seq 1} = \{ \ldots n_1, n_2, n_3, \ldots \} \) and \( \text{Seq 2} = \{ \ldots n_1, n_2, \ldots \} \). Here node 1 is the highest priority node at depth 1, and \( n_2 \) is one of its lower priority sibling in the same depth and thus yet not fetched, and \( n_3 \) is the new node at depth \( d \) exposed by the fetching of node 1. For removing some clutter in this proof, without losing the generality of proof, we also this time assume that the set of nodes between these switched nodes is empty. Let's also assume that

\[
p_{\text{seq1}} = \Pr[a_{n+1} = n_2 \mid a_n = A] \text{ and } p_3 = \prod_{i=1}^{d} \Pr[a_{i+1} = n_{i+1} \mid a_i = n_i].
\]

Thus, the cost corresponding to these sequences are respectively given by the following expressions.

\[
C_{\text{seq1}} = p_1 \cdot T_1 + p_2 \cdot (T_1 + T_2) + p_3 \cdot \max\{T_1 + T_2 + T_3 - (T_1 + R_1),0\} \tag{C.2}
\]
\[
C_{\text{seq2}} = p_1 \cdot T_1 + p_2 \cdot (T_1 + T_2 + T_3) + p_3 \cdot \max\{T_1 + T_2 - (T_1 + R_1),0\} \tag{C.3}
\]

In both of the cases, we begin counting the response delay for \( n_3 \) after \( n_1 \) is loaded and read. The proof that, \( C_{\text{seq1}} \leq C_{\text{seq2}} \) requires that we show under condition (1b):

\[
p_3 \cdot \max\{T_2 + T_3 - R_1,0\} \leq p_2 \cdot T_3 + p_3 \cdot \max\{T_3 - R_1,0\} \tag{C.4}
\]

Below, we show it by considering the following three cases.

Case 1: Let us consider that case, when, \( \max\{T_2 + T_3 - R_1,0\} = T_2 + T_3 - R_1 \), and \( \max\{T_3 - R_1,0\} = T_3 - R_1 \). Then the above reduces that we show that:

\[
p_3 (T_2 + T_3 - R_1) \leq p_2 \cdot T_3 + p_3 \cdot (T_3 - R_1), \text{ i.e. } p_3 \cdot T_2 \leq p_2 \cdot T_3, \text{ which is the case if } \frac{p_2}{T_2} \geq \frac{p_3}{T_3}
\]

Case 2: Let us consider that \( \max\{T_2 + T_3 - R_1,0\} = 0 \). Then we are required to show that \( p_3 \cdot \max\{T_2 + T_3 - R_1,0\} = 0 \leq p_2 \cdot T_3 + p_3 \cdot \max\{T_3 - R_1,0\} \), which is always the case.

Case 3: Let us consider the only remaining case where, \( \max\{T_2 + T_3 - R_1,0\} = T_2 + T_3 - R_1 \), but \( \max\{T_3 - R_1,0\} = 0 \). Then, \( T_3 - R_1 \leq 0 \) and we require to show that, \( p_3 \cdot (T_2 + T_3 - R_1) \leq p_2 \cdot T_3 \).
Since, \( T_3 - R_1 \leq 0 \), then to show \( p_3 \cdot (T_2 + T_3 - R_1) \leq p_2 \cdot T_3 \), thus it should be sufficient to show that \( p_3 \cdot T_2 \leq p_2 \cdot T_3 \). Which is the case if \( \frac{p_2}{T_2} \geq \frac{p_3}{T_3} \). Thus, for all situations \( C_{seq1} \leq C_{seq2} \) (proved).

**Theorem-3 (Graph Decision):** For general graph \( G(V_G,E_G) \) the node priority can be determined by computing order-n Markov state probability \( p_i \). For a node \( n_i \), with the estimated loading time \( T_i \) the priority function can be computed as:

\[
Q_i = \frac{p_i}{T_i} \quad \text{....(D.1)}
\]

Proof: Let us consider that a general graph, with link transition probabilities \( p_{ij} \) and state probabilities \( p_n \). Let the current anchor node is \( n_0 \). We again consider two nodes, both un-fetched, but one \( n_2 \) at depth 1 from current anchor that can be called immediately, and another \( n_3 \) somewhere deep in the graph, and which can be accessed via multiple paths and at least one preceding node of which have been fetched. Since, \( n_3 \) is now in the pre-fetch set, a root of \( n_3 \) must also be in the pre-fetch set with higher priority than \( n_3 \). Let this node be \( n_1 \). Let \( L(0,3) = \{ l_1, l_2, l_3, \ldots, l_n \} \) is the set of all the paths through which \( n_1 \) can be reached from \( n_0 \). Consequently, we consider two pre-fetching sequences Sequence 1 = [ … \( n_1, n_2, n_3, \ldots \) ] and Sequence 2= [ … \( n_1, n_2, n_3, \ldots \) ]. Also, for reducing some clutter in this proof, without loosing the generality of proof, we also this time assume that the set of nodes between these switched nodes is empty. Let \( \Pr(l = l_i | a_0 = n_0) \) is the probability of traversing path 0-2 via path \( l_i \). Let \( R(l) \) is the cumulative rendering time of all nodes in path \( l \) except \( n_3 \). Then the cost of sequence 1 and sequence 2 are respectively given by:

\[
C_{seq1} = p_2 \cdot (T_1 + T_2) + \sum_{l} \Pr(l = l_{03} | A_e = n_0) \cdot \max\left\{ t_1 + T_2 + T_3 - R(l_{03}), 0 \right\} \quad \text{....(D.2)}
\]

\[
C_{seq2} = p_2 \cdot (T_1 + T_2 + T_3) + \sum_{l} \Pr(l = l_{03} | A_e = n_0) \cdot \max\left\{ t_1 + T_2 - R(l_{03}), 0 \right\} \quad \text{....(D.3)}
\]

Note, there are other nodes involved along each path, each of which must be loaded and read before \( n_3 \) is reached. In a more precise sense, only after the current node has been requested by the user then the delay counter for the current node should begin. Thus D.3 overestimates the penalty by not issuing credit for the time needed in loading the preceding nodes along the path, which may or may not be already in the cache. (However, credit is issued for reading times). For fairness, however, we have taken out this credit in both the sequences. Now we consider the following cases:

Case A:
Now, if \( \max\left\{ t_1 + T_2 + T_3 - R(l_{03}), 0 \right\} = 0 \), then also true is \( \max\left\{ t_1 + T_3 - R(l_{03}), 0 \right\} = 0 \). Thus, \( C_{seq1} \leq C_{seq2} \) always.

Case B:
On the other hand, if \( \max \{ t_1 + T_3 - R(t_0') \cdot 0 \} = 0 \) then \( \max \{ t_1 + T_2 + T_3 - R(t_0') \cdot 0 \} \leq |T_2| \).

Thus,

\[
C_{seq1} \leq p_2 \cdot (T_1 + T_2) + \sum_{l} \Pr[I = l' \mid A_n = n_0] \cdot |T_2| = p_2 \cdot (T_1 + T_2) + p_3 \cdot |T_2|.
\]

\[
C_{seq2} = p_2 \cdot (T_1 + T_2 + T_3). \quad \text{Thus when, } p_3 \cdot T_2 \leq p_2 \cdot T_3, \text{ then also } C_{seq1} \leq C_{seq2}.
\]

Case C: otherwise:

\[
C_{seq1} = p_2 \cdot (T_1 + T_2) + p_3 \cdot (T_1 + T_2 + T_3) - \sum_{l} \Pr[I = l' \mid A_n = n_0] \cdot R(t_0')
\]

\[
C_{seq2} = p_2 \cdot (T_1 + T_2 + T_3) + p_3 \cdot (T_1 + T_3) - \sum_{l} \Pr[I = l' \mid A_n = n_0] \cdot R(t_0')
\]

Thus, when \( p_3 \cdot T_2 \leq p_2 \cdot T_3 \), then also \( C_{seq1} \leq C_{seq2} \) (proved).
